Case Study

ABSTRACT

Unguarded tricuspid orifice is a very rare anomaly. It is characterised by the absence of one or more of the tricuspid valve leaflets resulting in severe tricuspid regurgitation and right heart failure. It is rarely an isolated anomaly but more often associated with pulmonary atresia and intact ventricular septum. When the ventricles are inverted however, the result of outflow tract obliteration is not pulmonary atresia, but aortic atresia. This anomaly has been described in the literature in only 2 cases so far. We present a case of a neonate with unguarded tricuspid orifice with absence of all tricuspid leaflets, congenitally corrected transposition of the great arteries and aortic atresia. The severe tricuspid regurgitation and right ventricular enlargement would have required a Norwood-like procedure combined with a right ventricular plication. Due to the complexity of this lesion no surgical therapy was attempted in consent with the parents.

Keywords: Unguarded tricuspid orifice; congenitally corrected transposition of the great arteries; aortic atresia; pulmonary atresia with intact ventricular septum.

1. INTRODUCTION

An unguarded tricuspid orifice (UTO) is characterised by the absence of one or more of the tricuspid valve (TV) leaflets, the papillary muscles and chordae tendineae, while the fibrous ring is present at the atrioventricular junction [1]. The unguarded orifice leads to severe regurgitation. This anomaly was first described in 1938 by Klein [2] and since then precise descriptions of coexisting cardiac defects have been published. The most common associated lesion is pulmonary atresia with intact ventricular septum [3]. We describe a case of a neonate with congenital corrected transposition (ccTGA) and hence a left sided subaortic right ventricle (RV) with UTO.

2. CLINICAL SUMMARY

A full-term male neonate was referred to our clinic for further diagnostic workup. Prenatal examination diagnosed aortic atresia while the other aspects of the lesion were misinterpreted as mitral regurgitation. After vaginal delivery the child adopted well with mild tachypnea but stable circulation and sufficient oxygenation on room air. The duct was kept open with prostaglandins. Chest X-ray showed a significant cardiomegaly (Fig. 1). Postnatal echocardiography demonstrated a congenitally corrected transposition of the great arteries with aortic valve atresia and hypoplastic ascending aorta (Fig. 2-4 and video 1, 2). There was absence of all leaflets of the tricuspid valve by echocardiography (Fig. 5 and video 3). The fibrous ring was enlarged with a diameter of 17 mm. There was a 'to and fro' flow between the left atrium and the RV (video 4). The latter was dilated with myocardial thinning. A large atrial septal defect and a persistent arterial duct maintained the circulation. Left ventricular function was adequate. The outflow tract appeared narrowed, though without overt stenosis (Fig. 6). Prognosis was considered very poor. In consent with both parents palliative care therefore was initiated and the child died at the age of 6 days after termination of the prostaglandins.

The left ventricle is characterised by the absence of a moderator band and lack of septal attachments of a bicuspid valve. LV-left ventricle; RV-right ventricle; LA-left atrium; RA- right atrium
**3. DISCUSSION**

The association of unguarded tricuspid orifice with pulmonary atresia and intact ventricular septum is well known, albeit very rare [3]. Prognosis is poor and patients surviving the neonatal period undergo the Fontan pathway [4]. If a profound dilation of the right ventricle is present, plication of the RV prior to Fontan procedure has been described in cases of isolated UTO [5].

Clinical presentation of neonates with pulmonary atresia and intact ventricular septum and unguarded tricuspid orifice may have much in common with cases of Ebstein's malformation and distinguishing between those two entities by echocardiography can be challenging, especially in cases with partial agenesis of valvular tissue. Anderson et al. reviewed cases of Ebstein's malformation and UTO with associated dilation of the RV and found the difference between those two lesions by examining the mural leaflet of the tricuspid valve [6]. The latter is absent in patients with UTO but displaced in association with Ebstein's malformation. Agenesis of the tricuspid valvular tissue leads to unrestricted communication between the right atrium and ventricle resulting in a 'to and fro' flow across the atrioventricular junction [7].

Unguarded tricuspid orifice in ccTGA with atresia of the RVOT to the best of our knowledge has been described in only two cases in the literature so far [8, 9]. In contrast to our patient where all three leaflets were absent, in both previously described cases only the septal leaflet was absent. Both patients died due to intractable heart failure. In patients with ccTGA the RV is the systemic ventricle and thus atresia of the RVOT does not result in pulmonary, but aortic atresia. The aortic atresia and very hypoplastic ascending aorta would necessitate a Norwood-like procedure like in patients with hypoplastic left heart syndrome. In addition, the dilated RV probably would have required plication. Given the high risk of each of these procedures the risk in a combined approached was deemed as very high.

high and a palliative approach was chosen in consent with the parents. A post mortem was denied by the parents.

4. CONCLUSION

Unguarded tricuspid orifice is most often associated with pulmonary atresia and intact ventricular septum. Prognosis is worse than in PA-IVS alone [3]. In ccTGA however atresia of the RVOT results in aortic atresia making surgical correction even more complicated. Only three patients with this lesion have been described so far (including our case) with no survivor.
